Abstract

From the earliest months of life, infants prefer listening to and learn better from infant-directed speech (IDS) than adult-directed speech (ADS). Yet, IDS differs within communities, across languages, and across cultures, both in form and in prevalence. This large-scale, multi-site study used the diversity of bilingual infant experiences to explore the impact of different types of linguistic experience on infants' IDS preference. As part of the multi-lab ManyBabies 1 project, we compared lab-matched samples of 333 bilingual and 385 monolingual infants' preference for North-American English IDS (cf. ManyBabies Consortium, 2020 (ManyBabies 1)), tested in 17 labs in 7 countries. Those infants were tested in two age groups: 6–9 months (the younger sample) and 12–15 months (the older sample). We found that bilingual and monolingual infants both preferred IDS to ADS, and did not differ in terms of the overall magnitude of this preference. However, amongst bilingual infants who were acquiring North-American English (NAE) as a native language, greater exposure to NAE was associated with a stronger IDS preference, extending the previous finding from ManyBabies 1 that monolinguals learning NAE as a native language showed a stronger preference than infants unexposed to NAE. Together, our findings indicate that IDS preference likely makes a similar contribution to monolingual and bilingual development, and that infants are exquisitely sensitive to the nature and frequency of different types of language input in their early environments.

67   A multi-lab study of bilingual infants: Exploring the preference for infant-directed speech

68   When caregivers interact with their infants, their speech often takes on specific,

69 distinguishing features in a speech register known as infant-directed speech (IDS; Fernald et

70 al., 1989). IDS is produced by caregivers of most (although not all) linguistic and cultural

71 backgrounds, and is typically characterized by a slow, melodic, high-pitched, and

72 exaggerated cadence (Farran, Lee, Yoo, & Oller, 2016; Fernald et al., 1989; Kitamura,

73 Thanavishuth, Burnham, & Luksaneeyanawin, 2001; Pye, 1986; Shute & Wheldall, 1999).

74 From early in life, infants tune their attention to IDS, preferring to listen to IDS over

75 adult-directed speech (ADS) both at birth (Cooper & Aslin, 1990), as well as later in infancy

76 (Cooper, Abraham, Berman, & Staska, 1997; Cooper & Aslin, 1994; Fernald, 1985; Hayashi,

77 Tamekawa, & Kiritani, 2001; Kitamura & Lam, 2009; Newman & Hussain, 2006; Pegg,

78 Werker, & McLeod, 1992; Santesso, Schmidt, & Trainor, 2007; Singh, Morgan, & Best, 2002;

79 Werker & McLeod, 1989; Werker, Pegg, & McLeod, 1994).

80   Infants' preference for IDS may play a useful role in early language learning. For

81 example, infants are better able to discriminate speech sounds in IDS than in ADS (Karzon,

82 1985; Trainor & Desjardins, 2002), more efficiently segment words from continuous speech in

83 an IDS register (Thiessen, Hill, & Saffran, 2005), demonstrate better long-term memory for

84 words spoken in IDS (Singh, Nestor, Parikh, & Yull, 2009) and learn new words more

85 effectively from IDS than ADS (Graf Estes & Hurley, 2013; Ma, Golinkoff, Houston, &

86 Hirsh-Pasek, 2011; but see Schreiner, Altvater-Mackensen, & Mani, 2016).

87   While most studies have confirmed a general, early preference for IDS, to date there is

88 very little research aimed at understanding how different linguistic experiences affect infants'

89 preferences. For instance, although the existence of IDS has been demonstrated in a large

90 number of cultures (see above citations), the vast majority of the research on infants' IDS

91 preferences has been conducted in North America, using English speech typically directed at

North American English-hearing infants (Dunst, Gorman, & Hamby, 2012). Most critically, past work has been limited to a particular kind of linguistic (and cultural) experience: that of the monolingual infant. Here, we present a large-scale, multi-site, pre-registered study on bilingual infants, a population that is particularly suited to explore the relationship between language experience and IDS preference. Moreover, this research provides important insight into the early development of bilingual infants, a large but understudied population.

Does experience tune infants' preference for IDS?

What role might experience play in tuning infants' attention to IDS? We aggregated results from a recent published meta-analysis (Dunst et al., 2012) with additional community-contributed data (MetaLab, 2017) to examine their combined results. When all 62 studies are considered, we found a moderately-sized average effect of Cohen's $d =$.64. A focus on the 22 studies most similar to ours (testing IDS preference using looking times collected in a laboratory, among typically-developing infants from 3–15 months, with naturally-produced English-spoken IDS from an unfamiliar female speaker), the effect size is slightly lower, $d = .6$. Although this meta-analysis focused on infants in the first year of life, other studies of infants aged 18–21 months have also reported a preference for IDS over ADS (Glenn & Cunningham, 1983; Robertson, von Hapsburg, & Hay, 2013). There is some evidence that older infants show a greater preference for IDS than younger infants (Dunst et al., 2012), although an age effect was not found in the subsample of 22 studies mentioned above. More evidence is needed to explore the possibility that increased language experience as children grow enhances their preference for IDS.

Another variable that would be important in understanding the role of experience in the preference for IDS is whether the speech stimuli were presented in a native or non-native language. Numerous studies in early perception find different developmental trajectories for perception of native versus non-native stimuli (e.g. discriminating human faces

vs. discriminating monkey faces, Lewkowicz & Ghazanfar, 2006; discriminating native

vs. discriminating non-native speech sound categories, Maurer & Werker, 2014; segmenting

word forms from fluent speech, e.g., Polka & Sundara, 2012). Generally, whereas infants

show increasing proficiency in discriminating the types of faces and sounds that are present

in their environment, they lose sensitivity to the differences between non-native stimuli over

time. This general pattern might lead us to predict that infants will initially be sensitive to

differences between IDS and ADS in both the native and non-native languages, but that this

initial cross-linguistic sensitivity will decline with age. In other words, at some ages, infants'

preference for IDS over ADS could be enhanced when hearing their native language.

However, to date, there is very little data on this question. Importantly, this general trend, if

it exists, may interact with differences across languages in the production of IDS. The

exaggerated IDS of North American English might be either more interesting or less

interesting to an infant whose native language is characterized by a less exaggerated form

IDS, than for an infant who regularly hears North American English IDS.

Only a handful of IDS preference studies have explicitly explored infants' preference for

IDS from infants' native versus a non-native language. Werker et al. (1994) compared 4.5-

and 9-month-old English and Cantonese-learning infants' preference for videos of Cantonese

mothers using IDS versus ADS. Both groups showed a preference for IDS; however, the

magnitude of the preference between the two groups was not specifically compared (Werker

et al., 1994). Hayashi et al. (2001) studied Japanese-learning infants' (aged 4–14 months)

preference for native (Japanese) and non-native (English) speech. Japanese-learning infants

generally showed a preference for Japanese IDS over ADS, as well as an increasing preference

for Japanese IDS over English IDS. The latter finding shows that infants tune into their

native language with increased experience; however, as the study did not measure infants'

interest in English ADS, we do not know whether Japanese infants were equally sensitive to

the difference between ADS and IDS in the non-native stimuli, or whether/how this might

change over time.

Infants growing up bilingual are typically exposed to IDS in two languages. They provide a particularly useful wedge in understanding experiential influences on infants' attention to IDS. Bilingual infants receive less exposure to each of their languages than monolingual infants, and the exact proportion of exposure to each of their two languages varies from infant to infant. This divided exposure does not appear to slow the overall rate of language acquisition: bilinguals pass their language milestones on approximately the same schedule as monolingual infants, such as the onset of babbling and the production of their first words (Werker & Byers-Heinlein, 2008). Nonetheless, children from different language backgrounds receive different types of input, and must ultimately acquire different language forms, which can alter some patterns of language acquisition (e.g., Choi & Bowerman, 1991; Slobin, 1985; Tardif, 1996; Tardif, Shatz, & Naigles, 1997; Werker & Tees, 1984). As a consequence, bilingual infants allow researchers to investigate how a given "dose" of experience with a specific language relates to phenomena in language acquisition, while holding infants' age and total experience with language constant (Byers-Heinlein & Fennell, 2014).

Aside from the opportunity to study dose effects, it is important to examine the preference for IDS in bilingual infants for the sake of understanding bilingual development itself. Several lines of research suggest that early exposure to two languages changes some aspects of early development (Byers-Heinlein & Fennell, 2014), including bilinguals' perception of non-native speech sounds (i.e., sounds that are in neither of their native languages). For example, a number of studies have reported that bilinguals maintain sensitivity to non-native consonant contrasts (García-Sierra, Ramírez-Esparza, & Kuhl, 2016; Petitto et al., 2012; Ramírez, Ramírez, Clarke, Taulu, & Kuhl, 2017), tone contrasts (Graf Estes & Hay, 2015; Liu & Kager, 2017a), and visual differences between languages (i.e., rhythmic and phonetic information available on the face of talkers; Sebastián-Gallés, Albareda-Castellot, Weikum, & Werker, 2012) until a later age than monolinguals. Other studies have suggested that bilinguals' early speech perception is linked to their language

171 dominance (Liu & Kager, 2015; Molnar, Carreiras, & Gervain, 2016; Sebastián-Gallés &

172 Bosch, 2002), whereby bilinguals' perception most closely matches that of monolinguals in

173 their dominant language. Bilingual infants also demonstrate some cognitive differences from

174 monolinguals that are not specific to language, including faster visual habituation (Singh et

175 al., 2015), better memory generalization (Brito & Barr, 2014; Brito, Sebastián-Gallés, &

176 Barr, 2015), and greater cognitive flexibility (Kovács & Mehler, 2009a, 2009b). This might

177 reflect an early-emerging difference in information processing between the two groups.

178 Together, these lines of work raise the possibility that preference for IDS versus ADS could

179 have a different developmental course for bilingual and monolingual infants, and that

180 bilinguals' distinct course could interact with factors such as language dominance.

181 **Bilinguals' exposure to and learning from IDS**

182   Overall, there is very little research on whether bilinguals' experience with IDS is

183 comparable to monolinguals' experience. Some research has compared English monolinguals

184 and English-Spanish bilinguals in the United States (Ramírez-Esparza, García-Sierra, &

185 Kuhl, 2014, 2017). Here, researchers reported that bilingual infants around 1 year of age

186 received less exposure to IDS than monolingual infants on average. Moreover, in the

187 bilingual families, input was more evenly distributed across infant- and adult-directed

188 registers. It is difficult to know whether the results reported in these studies generalize to

189 other populations of bilinguals, or whether it was specific to this language community. As

190 acknowledged by the authors, the bilinguals in this study were of a lower SES than the

191 monolinguals, which could have driven differences in the amount of IDS that infants heard.

192 On the other hand, it might be the case that bilingual infants more rapidly lose their

193 preference for the IDS register than do monolinguals, and that caregivers of bilinguals

194 respond to this by reducing the amount of IDS input they provide.

195   Bilingual infants might also hear IDS that differs prosodically and phonetically from

196   that heard by monolingual infants. Bilingual infants often have bilingual caregivers, and

197   even when they are highly proficient speakers, their speech may vary from that of

198   monolinguals. One study compared vowels produced in the IDS of monolingual English,

199   monolingual French, and balanced French-English bilingual mothers living in Montreal

200   (Danielson, Seidl, Onishi, Alamian, & Cristia, 2014). Bilingual mothers' vowels were distinct

201   in the two languages, and the magnitude of the difference between French and English

202   vowels was similar to that shown by monolingual mothers. However, another study showed

203   that in a word-learning task, 17-month-old French-English bilinguals learned new words

204   better from a bilingual speaker than a monolingual speaker, even though acoustic

205   measurements did not reveal what dimension infants were attending to (Fennell &

206   Byers-Heinlein, 2014; similar findings were found in Mattock, Polka, Rvachew, & Krehm,

207   2010). Finally, a study of Spanish-Catalan bilingual mothers living in Barcelona found that

208   some mothers were more variable in their productions of a difficult Catalan vowel contrast

209   than monolingual mothers (Bosch & Ramon-Casas, 2011). Thus, bilingual infants may not

210   only differ in the amount of IDS they hear in a particular language relative to monolingual

211   infants, but different populations of bilingual infants may also vary in how similar the IDS

212   they hear is to monolingual-produced IDS in the same languages. This could, in turn, lead

213   to greater variability across bilinguals in their preference for IDS over ADS when tested with

214   any particular stimulus materials.

215   Regardless of bilingual infants' specific experience with IDS, evidence suggests that

216   bilinguals might enjoy the same learning benefits from IDS as monolinguals. For example,

217   Ramírez-Esparza et al. (2017) found that greater exposure to IDS predicted larger

218   vocabulary size in both monolingual and bilingual infants. Indeed, an untested possibility is

219   that exposure to IDS might be of particular benefit to bilingual infants. Bilinguals face a

220   more complex learning situation than monolinguals, as they acquire two sets of sounds,

221   words, and grammars simultaneously (Werker & Byers-Heinlein, 2008). This raises the

222   possibility that bilingual infants might have enhanced interest in IDS relative to

²²³ monolinguals, or that they might maintain a preference for IDS until a later age than

²²⁴ monolinguals, similiar to the extended sensitivity observed in bilingual infants' perception of

²²⁵ non-native phonetic contrasts.

²²⁶ Replicability in research with bilingual infants

²²⁷   Working with bilingual infant populations engenders unique replicability issues above

²²⁸ and beyond those common in the wider field of infant research (e.g., between-lab variability,

²²⁹ methodological variation, etc.; see Frank et al., 2017). These issues begin with the nature of

²³⁰ the population. Our discussion of bilingual infants thus far has used "bilingual" as a blanket

²³¹ term to describe infants growing up hearing two or more languages. However, this usage

²³² belies the large variability in groups of infants described as "bilingual". First, some studies of

²³³ bilinguals have included infants from a homogeneous language background (where all infants

²³⁴ are exposed to the same language pair; e.g. English-Spanish in Ramírez-Esparza et al., 2017),

²³⁵ while others have included infants from heterogeneous language backgrounds (where infants

²³⁶ are exposed to different language pairs, e.g., English-Other, where "Other" might be Spanish,

²³⁷ French, Mandarin, Punjabi, etc.; e.g., Fennell, Byers-Heinlein, & Werker, 2007). Second,

²³⁸ some bilinguals learn two typologically closely related languages (e.g. Spanish-Catalan) while

²³⁹ others learn two distant languages (e.g. English-Mandarin). Third, there is wide variability

²⁴⁰ between bilingual infants in the amount of exposure to each language, which introduces an

²⁴¹ extra dimension of individual difference relative to studies with monolingual infants. Fourth,

²⁴² studies define bilingualism in different ways, ranging from a liberal criterion of at least 10%

²⁴³ exposure to the non-dominant language to at least 40% exposure to the non-dominant

²⁴⁴ language (Byers-Heinlein, 2015). Finally, bilingual and monolingual populations can be

²⁴⁵ difficult to compare because of cultural, sociological, and socio-economic status differences

²⁴⁶ that exist between samples.

²⁴⁷   All of the above difficulties have resulted in very few findings being replicated across

different samples of bilinguals. The limited research that has compared different types of

bilingual learners has indicated that the particular language pair being learned by bilingual

infants influences speech perception of both native (Bialystok, Luk, & Kwan, 2005; Sundara

& Scutellaro, 2011) and non-native (Patihis, Oh, & Mogilner, 2015) sounds. In contrast,

other studies have not found differences between bilinguals learning different language pairs,

for example in their ability to apply speech perception skills to a word learning task (Fennell

et al., 2007). Generally, we do not know how replicable most findings are across different

groups of bilinguals, or how previously reported effects of bilingualism on learning and

perception are impacted by the theoretically interesting moderators discussed above.

Research on bilingual infants also faces many of the same general concerns shared with

other fields of infancy research, such as challenges recruiting sufficient participants to

conduct well-powered studies (Frank et al., 2017). Finding an appropriate bilingual sample

further limits the availability of research participants, even in locations with significant

bilingual populations. Such issues are particularly relevant given the recent emphasis on the

replicability and best practices in psychological science (Klein et al., 2014; Open Science

Collaboration, 2015; Simmons, Nelson, & Simonsohn, 2011). Of particular interest is

whether bilingual infants as a group show greater variability in their responses than

monolingual infants, and how to characterize the variability of responses between the

different types of samples of bilinguals that can be recruited by particular labs (i.e.,

homogeneous vs. heterogeneous samples). Understanding whether variability differs

systematically across groups is vital for planning appropriately-powered studies.

Description of the current study

Here, we report a large-scale, multi-site, pre-registered study aimed at using data from

bilingual infants to understand variability in infants' preference for IDS over ADS. This

study, "ManyBabies 1 Bilingual", is a companion project to the "ManyBabies 1" project,

published in a previous issue of this journal (ManyBabies Consortium, n.d.). The two studies

were conducted in parallel, using the same stimuli and experimental procedure. However,

while ManyBabies 1 analyzed all data collected from monolingual infants (including those

data from monolinguals reported here), the current study reports a subset of these data

together with additional data from bilingual infants not reported in that paper. Our

multi-site approach gives us precision in estimating the overall effect size of bilingual infants'

preference for IDS, while also allowing us to investigate how different types of language

experience moderate this effect.

Our primary approach was to compare bilinguals' performance to the performance of

monolinguals tested in the same lab. This approach has two notable advantages. First,

within each lab, bilinguals shared one of their two languages with monolinguals (the

language of the wider community). Second, testing procedures were held constant within

each lab. Thus, this approach allowed us to minimize procedural confounds with infants'

bilingual status. However, a disadvantage of this approach is that it leaves out data from

monolingual infants tested in other labs (since not all laboratories provided data from

bilingual infants), which could potentially add precision to the measured effects. Thus, we

performed additional analyses comparing all bilinguals to all monolinguals within the same

age bins, regardless of the labs each had been tested in.

We tested bilinguals in two of age windows: 6–9 months, and 12–15 months [1]. The

specific age bins selected were based on a preliminary survey of availability of the age ranges

from participating laboratories. The choice of non-adjacent age bins also increased the

chances of observing developmental differences.

All infants were tested using the same stimuli, which consisted of recordings of

North-American English (NAE) accented IDS and ADS. Because of the international nature

of this multi-site project, these stimuli were native for some infants but non-native for other

---

[1]Note that ManyBabies 1 also monolingual also tested 3-6 month and 9-12 month groups.

infants, both in terms of the language of the stimuli (English), and the variety of infant-directed speech (NAE-IDS is particularly exaggerated in its IDS characteristics relative to other varieties of IDS; see Soderstrom, 2007 for a review). Moreover, the stimuli were produced by monolingual mothers. Thus, infants' exposure to the type of stimuli used varied from low (monolinguals and bilinguals not exposed to NAE), to moderate (bilinguals learning NAE as one of their two languages), to high (monolinguals learning NAE).

Infants were tested in one of three experimental setups regularly used to test infant auditory preference: central fixation, eye-tracking, and headturn preference procedure. The use of a particular setup was the choice of each lab, depending on their equipment and expertise. Labs that tested both monolinguals and bilinguals used the same setup for both groups. On all setups, infants heard a series of trials presenting either IDS or ADS, and their looking time to an unrelated visual stimulus (e.g., a checkerboard) was used as an index of their attention. In central fixation, infants sat in front of a single screen that displayed a visual stimulus, and their looking was coded via button press using a centrally positioned camera while the auditory stimulus played. Eye-tracking was similar, except that infants' looking was coded automatically using a corneal-reflection eye-tracker. In the headturn preference procedure setup (HPP; see Kemler Nelson et al., 1995), infants sat in the middle of a room facing a central visual stimulus. Their attention was drawn to the left or right side of the room by a visual stimulus while the auditory stimulus played, and the duration of their looking was measured via button press using a centrally positioned camera.

Research questions

We identified three basic research questions addressed by this study. Note that it was not always possible to make specific predictions given the very limited data on infants' cross-language preferences for IDS over ADS, and particularly the absence of data from bilingual infants. We also note that the ManyBabies 1 project, focusing on monolingual

infants, addresses other more general questions such as the average magnitude of the IDS preference, changes in preference over age, and the effects of methodological variation (ManyBabies Consortium, n.d.). The main questions addressed by data from bilingual infants are:

1. How does bilingualism affect infants' interest in IDS relative to ADS? As described above, monolingual infants display an early preference for IDS that grows in strength at least through the first year of life. We anticipated that the bilingual experience might result in a different pattern of IDS preference; however, the direction and potential source of any difference is difficult to predict. For example, the more challenging nature of early bilingual environments might induce an even greater preference for IDS over ADS relative to monolinguals. This enhanced preference could be shown across development, or might be observed only at certain ages. On the other hand, given some evidence that parents of bilingual infants produce relatively less IDS than parents of monolingual infants, it may be that bilinguals show less interest in IDS than monolinguals. We also explored the following questions as potential sources for an emerging difference between populations: If an overall difference between monolingual and bilingual infants' preference for IDS is observed, can this be accounted for by systematic differences in socioeconomic status? Do bilinguals show greater variability in their preference for IDS than monolinguals?

2. How does the amount of exposure to NAE-IDS affect bilingual infants' listening preferences? While we expected infants across different language backgrounds to show greater interest in IDS over ADS, we investigated whether this was moderated by the amount of exposure to NAE. For monolinguals, this exposure would be either 100% (monolingual learners of NAE) or 0% (monolingual learners of other languages). For bilinguals, some infants would have 0% exposure to NAE-IDS (e.g., bilingual infants learning Spanish and Catalan) while others would have a range of different exposures

349 (e.g., bilingual infants learning NAE and French). This allowed us to at least partially

350 disentangle dose effects of exposure to NAE-IDS from infants' bilingualism. An

351 additional possibility is that infants' exposure to NAE would predict overall attention

352 to both infant-directed and adult-directed NAE, with no differential effects on interest

353 to IDS versus ADS. Finally, it is possible that NAE-IDS is equally engaging to infants

354 regardless of their experience with North American English.

355 3. Finally, we had planned to ask how bilingual infants' listening to NAE-IDS and ADS

356 impacted by the particular language pair being learned. We intended to ask this

357 question at both the group and at the individual level. At the group level, we planned

358 to investigate whether different patterns of results would be seen in homogeneous

359 versus heterogeneous samples of bilinguals, in terms of overall preference for IDS and

360 group-level variability. However, ultimately we had insufficient homogeneous samples

361 to address this question. At the individual level, we were interested in how the

362 particular language pair being learned modulated infants' preference for IDS. As we

363 did not know a priori what language pairs would have sufficient sample size for

364 analysis, this was considered a potential exploratory analyses. Ultimately, due to the

365 nature of our main results and the diverse language backgrounds of our final sample,

366 we decided to leave this question open for future investigations.

Methods

Participation Details

369 Our monolingual sample originated from the ManyBabies 1 project (ManyBabies

370 Consortium, 2020). Here we report some basic information about that sample - the reader is

371 referred to the original study for further details, and focus primarily on the bilingual sample.

372 We report how we determined our sample size, all data exclusions, all manipulations, and all

373 measures in the study.

374   **Time-frame.**   An open call for labs to participate was issued on February 2, 2017.

375 Participant testing began on May 1, 2017. Testing for monolinguals ended on April 30, 2018.

376 Because of the additional difficulty of recruiting bilingual samples, the end-date for collection

377 of these data was extended by four months to August 31, 2018. Due to a miscommunication,

378 one lab continued testing data beyond this deadline but prior to data analysis, and these

379 data were included in the final sample.

380   **Age distribution.**   Labs contributing data from bilingual infants were asked to test

381 participants in at least one of two (but preferably both) age bins: 6–9 month-olds (6:1 – 9:0)

382 and 12–15 month-olds (12:1 – 15:0). Labs were asked to aim for a mean age at the centre of

383 the bin, with distribution across the entire age window.

384   **Lab participation criterion.**   Considering the challenges associated with recruiting

385 bilingual infants and the importance of counterbalancing in our experimental design, we

386 asked labs to contribute a minimum of 16 infants per age and language group (note that

387 infants who met inclusion criteria for age and language exposure but were ultimately

388 excluded for other reasons counted towards this minimum N). We also expected that

389 requiring a relatively low minimum number of infants would encourage more labs to

390 contribute a bilingual sample, and under our statistical approach a larger number of groups

391 is more important than a larger number of individuals (Maas & Hox, 2005). However, labs

392 were encouraged to contribute additional data provided that decisions about when to stop

393 data collection were made ahead of time (e.g., by declaring an intended start and end date

394 before data collection). A sensitivity analysis showed that, with a sample of 16 infants and

395 assuming the average effect size of similar previous studies (Cohen's d = .7; Dunst et al.,

396 2012; MetaLab, 2017), individual labs would have 74% power to detect a preference for IDS

397 in a paired-samples t-test (alpha = .05, one-tailed). Assuming a smaller effect size of

398 Cohen's d = 0.6, a conservative estimate of power based on the literature reviewed above,

individual labs' power would be 61%. The moderate statistical power that individual labs would have to detect this effect highlights the importance of our approach to combine data across labs. We note that some labs were unable to recruit their planned minimum sample of 16 bilingual infants that met our inclusion criteria in the timeframe available, a point we will return to later in the paper.

Labs were asked to screen infants ahead of time for inclusion criteria, typically by briefly asking about language exposure over the phone. Despite this screening process, some infants who arrived in the lab for testing fell between the criteria for monolingual and bilingual status based on the comprehensive questionnaire. In such cases, the decision whether to test the infant was left up to individual laboratories' policy, but we asked that data from any babies who entered the testing room be submitted for data processing (even though some such data might be excluded from the main analyses).

Ethics.   Each lab followed the ethical guidelines and ethics review board protocols of their own institution. Labs submitted anonymized data for central analysis that identified participants by code only. Video recordings of individual participants were coded and stored locally at each lab, and where possible were uploaded to a central controlled-access databank accessible to other researchers.

Participants

Defining bilingualism.   Infants are typically categorized as bilingual as a function of their parent-reported relative exposure to their languages. However, studies vary considerably in terms of inclusion criteria for the minimum exposure to the non-dominant language, which in previous studies has ranged from 10% to 40% of infants' exposure (Byers-Heinlein, 2015). Some bilingual infants may also have some exposure to a third or fourth additional language. Finally, infants can vary in terms of when the onset of exposure

to their additional languages is, which can be as early as birth or anytime thereafter. We aimed to take a middle-of-the-road approach to defining bilingualism, attempting to balance a need for experimental power with interpretable data.

Thus, we asked each participating lab to recruit a group of simultaneous bilingual infants who were exposed to two languages between 25% and 75% of the time, with regular exposure to both languages beginning within the first month of life. There was no restriction as to whether infants were exposed to additional languages, thus some infants could be considered multilingual (although we continue to use the term bilingual throughout this manuscript). These criteria would include, for example, an infant with 40% English, 40% French, and 20% Spanish exposure, but would exclude an infant with 20% English, 70% French, and 10% Spanish exposure. We also asked labs to recruit a sample of bilingual infants who shared at least one language – the community language being learned by monolinguals tested in the same lab. For labs in bilingual communities (e.g., Barcelona, Ottawa, Montréal, Singapore), labs were free to decide which community language to select as the shared language. Within this constraint, most labs opted to test heterogeneous groups of bilinguals, for example, English-Other bilinguals where English was the community language the other language might be French, Spanish, Mandarin, etc. Only one lab tested a homogeneous group of bilinguals (in this case, all infants were learning English and Mandarin), although we had expected that more labs would test homogeneous samples, given both heterogeneous and homogeneous samples are used regularly in research with bilingual infants. Because only one homogeneous sample was tested, we were not able to conduct planned analyses examining whether the type of sample on our results. Infants that were tested but that did not meet inclusion criteria into the group (for example because they did not hear enough of their non-dominant language, or were not hearing the community language) were excluded from the main analyses, but retained for exploratory analyses where appropriate.

449   **Assessing bilingualism.**   Each lab was asked to use a detailed day-in-the-life

450 parental interview questionnaire to quantify the percent of time that infants were exposed to

451 each language. This approach has been shown to predict bilingual children's language

452 outcomes better than a one-off parental estimate (DeAnda, Bosch, Poulin-Dubois, Zesiger, &

453 Friend, 2016). Moreover, recent findings based on day-long recording gathered using LENA

454 technology show that caregivers can reliably estimate their bilingual child's relative exposure

455 to each language (Orena et al., 2019). Labs were also asked to pay special attention to

456 whether infants had exposure to North American English (based on a parent report of the

457 variety of English spoken to their infant), and if so which caregiver(s) this input came from.

458 As most of the labs contributing bilingual data had extensive expertise in bilingual language

459 background assessment, we encouraged each lab to use whatever version of measurement

460 instrument was normally used in their lab (details of the assessment instruments are outlined

461 below, including source references for most measures). Where possible, labs conducted the

462 interview in the parents' language of choice, and documented whether the parents' preferred

463 language was able to be used.

464   While standardization of measurement tools is often desirable, we reasoned that

465 different questions and approaches might be best for eliciting information from parents in

466 different communities and from different cultures. Indeed, many labs reported that their own

467 instruments had undergone considerable refinement over the years as a function of their

468 experience working with the families in their communities. However, in order to maximize

469 the overall sample size and the diversity of bilingual groups tested, we encouraged

470 participation from laboratories without extensive experience testing bilingual infants. Labs

471 that did not have an established procedure were paired with more experienced labs working

472 with similar communities to refine a language assessment procedure. Twelve of the labs

473 administered a structured interview-style questionnaire based on the one developed by Bosch

474 and Sebastián-Gallés (1997, 2001; for examples of the measure see the online supplementary

475 materials of Byers-Heinlein et al., 2019; DeAnda et al., 2016), and the remaining 5 labs

administered other questionnaires. We describe each of these approaches in detail below.

The Bosch and Sebastián-Gallés (1997, 2001) questionnaire is typically referred to in the literature as the Language Exposure Questionnaire (LEQ; e.g., Byers-Heinlein, Fennell, & Werker, 2013), or the Language Exposure Assessment Tool (LEAT; DeAnda et al., 2016). Administration of these questionnaires takes the form of a parental interview, where a trained experimenter systematically asks at least one of the infant's primary caregivers detailed questions about the infant's language environment. The interviewer obtains an exposure estimate for each person who is in regular contact with the infant, as defined by a minimum contact of once a week. For each of those people, the caregiver gives an estimate of how many hours per day they speak to the infant in each language for each of the days of the week (e.g., weekdays and weekends may differ depending on work commitments). Further, the caregiver is asked if the language input from each regular-contact person was similar across the infant's life history. If not, such as in the case of a caregiver returning to work after parental leave, or an extended stay in another country, an estimate is derived for each different period of the infant's lifespan. The interviewer also asks the caregiver about the language background of each person with regular contact with the infant (as defined above), asking the languages they speak and whether they are native speakers of those languages. The caregiver also gives an estimate of language exposure in the infant's daycare, if applicable. Finally, the caregiver gives a global estimate of their infant's percent exposure to the two languages, which includes input from those people in regular contact with the infant and other people with whom the infant has less regular contact (e.g., playgroups, friends of caregivers, etc.). Importantly, this global estimate does not include input from television or radio, as such sources have no known positive impact, and may even have a negative impact on monolingual and bilingual language development in infancy (see Hudon, Fennell, & Hoftyzer, 2013). The estimate of an infant's percent exposure to their languages is derived from the average cumulative exposure based on the data from the primary individuals in the infant's life. Some labs use the global estimate simply to confirm these

percentages. Other labs average the primary and global exposure to take into account all language exposure, while still giving more weight to the primary individuals. Also, some labs asked additional questions, for example about videoconferencing with relatives, whether caregivers mix their languages when speaking to the infant, or caregivers' cultural background. Finally, while the original form was pen-and-paper, there have been adaptations which include using a form-fillable Excel sheet (DeAnda et al., 2016).

For the other language exposure measures used by 5 of the labs, we will simply highlight the differences from the LEQ/LEAT measure described above, as there is much overlap between all the instruments used to measure infants' exposure to their languages. Two labs used custom assessment measures designed within each lab. The major difference from the LEQ for the first of these custom measures is that parents provide percentage exposure estimates for each language from primary individuals in the infant's life, rather than exposure estimates based on hours per day in each language. The other custom measures, unlike the LEQ, specifies estimates of language exposure in settings where more than one speaker is present by weighting each speaker's language contribution. A further two labs used other child language exposure measures present in the literature: one used the Multilingual Infant Language Questionnaire (MILQ; Liu & Kager, 2017b) and the other used an assessment measure designed by Cattani et al. (2014). For the MILQ, one major difference is that parents complete the assessment directly using an Excel sheet with clear instructions. The other major difference is that the MILQ is much more detailed than the LEQ/LEAT: breaking down language exposure to very specific activities (e.g., car time, book reading, meal time); asking more detail about the people in regular contact with the infant (e.g., accented speech, level of talkativeness); and obtaining estimates of media exposure (e.g., TV, music). The measure from Cattani et al. (2014) focuses on parental exposure and uses Likert scales to determine exposure from each parent. The ratings are converted to percentages and maternal exposure is weighted more in the final calculation based on data showing that mothers are more verbal than fathers. Finally, one lab did not use a detailed

measure, but rather simply asked parents to give an estimate of the percentage exposure to each of the languages their infant was hearing.

For monolinguals, labs either did the same assessment with bilinguals, or minimally check participants' monolingual status by asking parents a single question: estimate the percent of time that their infant was exposed to their native language. Under either approach, if that estimate exceeded 90% exposure to a single language, the infant was considered monolingual.

Demographics. Each lab administered a questionnaire that gathered basic demographic data about infants, including age, health history, gestation, etc. Infants' socioeconomic status (SES) was measured via parental report of years of maternal education. To standardize across different education systems where formal schooling may begin at different ages, we counted the number of years of education after kindergarten. For example, in the United States, mothers who had completed high school would be considered to have 12 years of education.

Final sample. Our final sample of bilinguals who met our infant-level inclusion criteria included 333 infants tested in 17 labs; 148 were 6–9 months, and 185 were 12–15 months (full account of exclusions is detailed in the results section). These 17 labs also collected data from monolingual infants (N = 385 who met infant-level inclusion criteria), of whom 182 were 6–9 months, and 203 were 12–15 months. While all analyses required that data meet the infant-level inclusion criteria, some analyses further required that the data met the lab-level inclusion criteria (lab-level inclusion criteria are discussed in the Results section where they were implemented for specific analyses). Data from monolingual infants in these age ranges were available from 59 additional labs (n = 583 6-9 month-olds; n = 468 12-15 month-olds) who did not contribute bilingual data. Bilingual infants and lab-matched monolingual samples tested by each lab are detailed in Table 1. For further description of our participants, please refer to the Appendix, where we list gender distributions across

556   subsamples (Table A1) and the language pairs being learned by bilingual infants (Table A2).

Table 1

Number of monolingual and bilingual infants in each age group which met infant-level inclusion criteria, average years of maternal education (SES), and average NAE exposure for blingual infants by lab. Note that because of lab-level inclusion criteria, cells with n < 10 were excluded from the meta-analytic analyses, but were included in the mixed-effects regression analyses. Labs that only tested monolingual infants are not listed.

Materials

Visual stimuli.   Labs using a central fixation or eye-tracking method presented infants with a brightly-coloured checkerboard as the main visual stimulus. A video of a laughing baby was used as an attention-getter between trials to reorient infants to the screen. Labs using the headturn preference procedure used the typical visual stimulus employed in their labs, which was sometimes light bulbs (consistent with the original development of the procedure in the 1980s) or sometimes colourful stimuli presented on LCD screens. All visual stimuli are available via the ManyBabies 1 Open Science Framework site at osf.io/re95x/.

Auditory stimuli.   Auditory stimuli consisted of semi-naturalistic recordings of mothers interacting with their infants (ranging in age from 122–250 days) in a laboratory setting. Mothers were asked to talk about a set of objects with their infant, and also separately with an experimenter. A set of 8 IDS and 8 ADS auditory stimuli of 20 s each were created from these recordings. Details regarding the recording and selection process, acoustic details and ratings from naive adult listeners can be found in the ManyBabies 1 study (ManyBabies Consortium, n.d.) and the associated Open Science Framework project at osf.io/re95x.

Procedure

Basic Procedure.   Each lab used one of three common infant study procedures, according to their own expertise and the experimental setups available in the lab: central fixation (3 labs), eye-tracking (7 labs), or headturn preference procedure (7 labs). The testing procedure was identical to that used in the ManyBabies 1 project (ManyBabies Consortium, n.d., deviations from the protocol are also described there), and only key aspects will be briefly summarized here.

Infants sat on their parents' laps or in a high chair, and parents listened to masking

music over headphones throughout the study. Infants saw 2 training trials that presented an unrelated auditory stimulus (piano music), followed by 16 test trials that presented either IDS or ADS speech. Trials were presented in one of four pseudo-random orders that counterbalanced the order of presentation of the two stimulus types. Note that within each order, specific IDS and ADS clips were presented adjacently in yoked pairs to facilitate analyses. On each trial, the auditory stimulus played until the infant looked away for 2 consecutive seconds (for labs that implemented an infant-controlled procedure) or until the entire stimulus played, up to 19 seconds (for labs that implemented a fixed trial-length procedure). The implementation of the procedure depended on the software that was available in each lab. Trials with less than 2 seconds of looking were excluded from analyses. Attention-grabbing stimuli were played centrally between trials to reorient infants to the task.

The main differences between the setups were the type and position of visual stimuli presented, and the onset of the auditory stimuli. For central fixation and eye-tracking procedures, infants saw a checkerboard on a central monitor, whose presentation coincided with the onset of the auditory stimuli on each trial. For the headturn preference procedure, the visual stimulus (either flashing light bulbs or a colourful stimulus) played silently on a monitor/bulb in the centre of the room and on one of two side monitors/bulbs, and the auditory stimulus began playing when the infant turned their head towards the side stimulus.

The dependent variable was infant looking time during each trial. For eye-tracking setups, looking time was measured automatically via corneal reflection. For central fixation and headturn preference procedure setups, looking time was measured by trained human coders who were blind to trial type, according to the lab's standard procedures.

Parents completed questionnaires about participants' demographic and language background either prior to or after the main experiment.

Results

Analysis overview

Data exclusion. Labs were asked to submit all data collected as part of the bilingual study to the analysis team, and this section focuses on exclusions for infants collected as part of the bilingual sample. The initial dataset contained 706 bilingual infants, of which 333 met each of the following inclusion criteria. These criteria are detailed below. We note that exclusions were applied sequentially (i.e., percentages reflect exclusions among remaining sample after previous criteria were applied).

- *Full-term.* We defined full term as gestation times greater than or equal to 37 weeks. There were 4 (1.11%) bilingual infants who were tested but did not meet this criterion.

- *No diagnosed developmental disorders.* We excluded infants whose parents reported developmental disorders (e.g., chromosomal abnormalities, etc.) or were diagnosed with hearing impairments. There were 2 (0.56%) infants who were tested but did not meet this criterion. Due to concerns about the accuracy of parent reports, we did not plan exclusions based on self-reported ear infections unless parents reported medically-confirmed hearing loss.

- *Age.* We included infants in two age groups: 6-9 and 12-15 month-olds. There were 59 (11.78%) bilingual infants who were tested in the paradigm, but who fell outside our target ages.

- *Bilingualism.* We excluded infants from the bilingual sample whose language background did not meet our pre-defined criteria for bilingualism (see above for details). There were 74 (16.74%) infants whose exposure did not meet this criterion. We also excluded an additional 7 (1.90%) infants who met this criterion, but who were not learning the community language as one of their languages.

629   • *Session-level errors.* Participants were also excluded on the basis of session-level errors,

630   including 2 infants for equipment error, 1 infants for experimenter error and 3 infants

631   for outside interference.

632   • *Adequate trials for analysis.* We excluded any infant who did not have at least one

633   IDS-ADS trial pair available for analysis: 5 (1.45%) infants were tested but did not

634   meet these criteria. For infants with at least one good trial pair, we additionally

635   excluded any trial with less than 2 s of looking (n = 890 trials; 16.92%), which was set

636   as a trial-level minimum so that infants had heard enough of the stimulus to

637   discriminate IDS from ADS. As infants did not have to complete the entire experiment

638   to be included, this meant that different infants contributed different numbers of trials.

639   On average, infants contributed 15.67 trials to the analysis.

640   **Data analysis framework.**   All planned analyses were pre-registered at

641 https://osf.io/zauhq/; data and code are available at

642 https://github.com/manybabies/mb1b-analysis-public. Our primary dependent variable of

643 interest was looking time (LT), which was defined as the time spent fixating on the visual

644 stimulus during test trials. Given evidence that looking times are non-normally distributed,

645 we log-transformed all looking times prior to statistical analysis in the mixed effects model

646 (Csibra, Hernik, Mascaro, Tatone, & Lengyel, 2016). We refer to this transformed variable as

647 "log LT". For the meta-analysis, we analyzed effect sizes computed from raw difference scores,

648 which did not require log -transformation. We pre-registered a set of analyses to examine

649 whether monolinguals, heterogeneous samples of bilinguals, and homogeneous samples of

650 bilinguals showed different levels of variability. Unexpectedly, only 1 lab (Table 1) tested a

651 homogenous sample of bilinguals, thus we deviated from our original plan and did not

652 analyze data as a function of whether our bilingual groups were homogenous versus

653 heterogeneous. For the main analyses, we adopted two complementary data analytic

654 frameworks parallel to the ManyBabies 1 project (ManyBabies Consortium, n.d.):

655 meta-analysis and mixed-effects regression.

656   Under the meta-analytic framework, data from each sample of infants (e.g., 6 to 9

657 month-old bilinguals from Lab 1) was characterized by a) its effect size (here Cohen's *d*), and

658 b) its standard deviation. Effect size analyses addressed questions about infants' overall

659 preference for IDS, while group-based standard deviation analyses addressed questions about

660 whether some groups of infants show higher variability in their preference than others. Note

661 that meta-analyses of intra-group variability are relatively rare (Nakagawa et al., 2015;

662 Senior, Gosby, Lu, Simpson, & Raubenheimer, 2016). Unfortunately, our pre-registration did

663 not account for the eventuality that several labs contributed very small numbers of infants to

664 certain groups. In two cases where a lab contributed data with a single infant in a particular

665 language group, we were not able to it was impossible to compute an effect size. Thus, we

666 implemented a lab-level inclusion criterion for the meta-analysis such that each effect size

667 was computed only if the lab had contributed at least 10 infants in that particular language

668 group and age. For example, if lab A had contributed 7 bilingual infants between 6- to

669 9-months and 15 monolingual infants between 6- to 9-months, we only computed the effect

670 size for the monolingual group, but not for the bilingual group. This criterion ensured that

671 each effect size was computed based on a reasonable sample size (i.e., a minimum of 10

672 infants) and also was consistent with the lab-level inclusion criteria in the ManyBabies 1

673 study. Because this exclusion criterion was not part of the pre-registration, we also ran a

674 second analysis with a minimum contribution of 5 infants, which yielded very similar findings

675 (analysis cods and results can be found at our Github repository).

676   An advantage of the meta-analytic approach is that it is easy to visualize lab-to-lab

677 differences. Further, the meta-analytic framework most closely mirrors the current approach

678 for studying monolingual-bilingual differences, which typically compares groups of

679 monolingual and bilingual infants tested within the same lab. We used this approach

680 specifically to test the overall effect of bilingualism and its possible interactions with age on

the magnitude of infants' preference for IDS over ADS. We also compared standard

deviations for the bilingual group and monolingual group in a meta-analytic approach. This

analysis closely followed Nakagawa et al. (2015).

Under the mixed-effects regression model, trial-by-trial data from each infant were

submitted for analysis. Further, independent variables of interest could be specified on an

infant-by-infant basis. This approach had the advantage of potentially increasing statistical

power, as data are analyzed at a more fine-grained level of detail. As with the meta-analytic

approach, this analysis tested the effects of bilingualism and their potential interactions with

age. We also investigated whether links between bilingualism and IDS preference were

mediated by socio-economic status. Additionally, this approach allowed us to assess how the

amount of exposure to NAE-IDS, measured as a continuous percentage, affected infants'

listening preferences. Note that unlike for the meta-analysis, we did not apply a lab-level

inclusion criterion in order to maximize our sample size. Thus, data from all infants who met

the infant-level criteria were included in this analysis, resulting in slightly different sample

sizes under the meta-analytic and mixed-effects approaches.

Under both frameworks, we used a dual analysis strategy to investigate how infants'

IDS preference is related to bilingualism. First, we examined the lab-matched subset of data

from labs that contributed a monolingual and bilingual sample at a particular age. Second,

we examined the complete set of data including data from labs that contributed both

monolinguals and bilinguals, as well as additional data from labs that only tested

monolinguals at the ages of interest as part of the larger ManyBabies 1 project.

Confirmatory analysis section

Meta-analytic approach..   This approach focused on the analysis of group-level

datasets. We defined a dataset as a group of at least 10 infants tested in the same lab, of the

₇₀₅ same age (either 6-9 or 12-15 months), and with the same language background

₇₀₆ (monolingual or bilingual). For analyses of within-group variability, we compared bilingual

₇₀₇ infants to monolingual infants.

₇₀₈   To estimate an effect size for each dataset, we first computed individual infants'

₇₀₉ preference for IDS over ADS by 1) subtracting looking time to the ADS stimulus from

₇₁₀ looking time to the IDS stimulus within each yoked trial pair, and 2) computing a mean

₇₁₁ difference score for each infant. Pairs that had a trial with missing data were excluded

₇₁₂ (42.93% pairs in lab-matched dataset, 40.34% pairs in full dataset), which constituted a total

₇₁₃ of 30.77% of trials in lab-matched dataset, 31.02% of trials in full dataset. Note that we

₇₁₄ expected many infants to have missing data particularly on later test trials, given the length

₇₁₅ of the study (16 test trials). Then, for each dataset (i.e., combination of lab, infant age

₇₁₆ group, and whether the group of participants was bilingual or monolingual), we calculated

₇₁₇ the mean of these difference scores (M_d) and its associated standard deviation across

₇₁₈ participants (*sd*). Finally, we used the derived M_d and *sd* to compute a within-subject

₇₁₉ Cohen's *d* using the formula $d_z = M_d/sd$.

₇₂₀   In the following meta-analyses, random effects meta-analysis models with a restricted

₇₂₁ maximum-likelihood estimator (REML) were fit with the *metafor* package (Viechtbauer,

₇₂₂ 2010). To account for the dependence between monolingual and bilingual datasets stemming

₇₂₃ from the same lab, we added laboratory as a random factor. As part of our pre-registered

₇₂₄ analyses, we planned to include method as a moderator in this analysis if it was found to be

₇₂₅ a statistically significant moderator in the larger ManyBabies 1 project - which it was

₇₂₆ (ManyBabies Consortium, n.d.). However, because only 17 labs contributed bilingual data,

₇₂₇ we deviated from this plan because of the small number of labs per method (e.g., only three

₇₂₈ labs used a single-screen method).

₇₂₉   ***Effect size-based meta-analysis..***

730   Our first set of meta-analyses focused on effect sizes (d_z): how our variables of interest

731 contributed to effect size comparing looking time to IDS versus ADS trials. As a reminder,

732 we ran the analyses in two ways: (i) the analysis was only restricted to the labs that

733 contributed lab-matched data (lab-matched dataset), and (ii) the analysis included all

734 available data labs that tested only monolinguals or only bilinguals at the ages of interest

735 (full dataset).

736   We initially fit the following model to examine contributions of age and bilingualism to

737 infants' IDS preference, as well as potential interactions between these variables:

$$d_z \sim 1 + \text{bilingual} + \text{age} + \text{bilingual} * \text{age}$$

738   Bilingualism was dummy coded (0 = monolingual, 1 = bilingual), and age (a

739 continuous variable) was coded as the average age for each lab's contributed sample for each

740 language group (centered for ease of interpretation).

741   In the lab-matched dataset, we did not find any statistically significant effects of age

742 ($d_z = 0.17$, CI = [-1.01, 1.36], z = 0.29, $p = .775$), bilingualism ($d_z = $ -0.17, CI = [-0.44,

743 0.10], z = -1.22, $p = .224$), or interactions between age and bilingualism ($d_z = $ -0.19, CI =

744 [-1.84, 1.46], z = -0.22, $p = .822$).

745   Similarly, in the full dataset, we did not find any significant main effects of age, ($d_z = $

746 0.01, CI = [-0.65, 0.67], z = 0.02, $p = .982$), bilingualism ($d_z = $ -0.10, CI = [-0.29, 0.09], z =

747 -1.04, $p = .299$), nor a significant interaction between age and bilingualism ($d_z = 0.01$, CI =

748 [-0.93, 0.95], z = 0.02, $p = .981$).

749   As bilingualism is the key moderator of research interest in the current paper, here we

750 report the effect sizes of monolingual and bilingual infants separately. In the lab-matched

751 dataset, the effect size for monolinguals was $d_z = 0.42$ (CI = [0.21, 0.63], z = 3.94, $p < .001$),

752 while for bilinguals the effect was $d_z = 0.24$ (CI = [0.06, 0.42], z = 2.64, $p = .008$). In the

753 full dataset, the effect size for monolinguals was $d_z = 0.36$ (CI = [0.28, 0.44], z = 9.20,

754 $p < .001$), while for bilinguals the effect was $d_z = 0.26$ (CI = [0.09, 0.43], z = 2.97, $p = .003$).

755 In sum, numerically monolinguals showed a stronger preference for IDS than bilinguals, but

756 this tendency was not statistically significant in the effect size-based meta-analyses. A forest

757 plot for this meta-analysis is shown in Figure 1.

758   ***Within-group variability meta-analysis.***

759   Our second set of pre-registered meta-analyses examined whether the variability in

760 infants' preference for IDS within a sample (within-study variability) was related to language

761 background (monolingual vs. bilingual). Note that this question of within-sample

762 heterogeneity is different than questions of between-sample heterogeneity that can also be

763 addressed in meta-analysis (see Higgins & Thompson, 2002; Higgins, Thompson, Deeks, &

764 Altman, 2003 for approaches to between-group variability in meta-analysis). Specifically, the

765 within-group variability meta-analysis approach provides additional insights of how two

766 groups differ in terms of their variances, not merely their mean effect sizes. This approach is

767 useful when the language backgrounds of the infants influence not only the magnitude of

768 infants' IDS preference, but also the variability of infants' IDS preference. In the following,

769 the standard deviations measure looking time variability of infants' preference for IDS over

770 ADS in each language group (either monolingual or bilingual). Again, we report d_z, an effect

771 size that measures the magnitude of infants' preference for IDS over ADS.

772   Our pre-registered plan was to follow Nakagawa et al. (2014) and Senior et al. (2015).

773 According to Nakagawa et al. (2015), there are two approaches to run within-group

774 variability meta-analysis: one approach uses $lnCVR$, the natural logarithm of the ratio

775 between the coefficients of variation, to compare the variability of two groups; a second

776 approach enters $lnSD$ (the natural logarithm of standard deviations) and $ln\bar{X}$ (the log

777 mean) into a mixed-effect model. When data meet the assumption that the standard

778 deviation is proportional to the mean (i.e., the two are correlated), the first approach should
Figure 1. Forest plot for the lab-matched dataset, separated by age group. Standardized effect sizes are shown for each lab, with error bars showing 95% confidence intervals. Each lab reported two effect sizes: one for the monolingual group (red triangles) and the other one for the bilingual group (blue circles). Within each age group, points are ordered by the difference between the monolingual and bilingual effect sizes, and this effect size difference is indicated by a black X. Points are scaled by inverse variance (i.e., more precise estimates are denoted by larger shapes). The points in the bottom panel show the global meta-analytic estimate.

be used, and otherwise, the second approach should be used. Our data did not meet the

necessary assumption, therefore we used the second, mixed-effect approach. In the following

meta-regression model, the natural logarithm of the standard deviations ($lnSD$) from each

language group is the dependent variable. This dependent variable (group variance) is the

log-transformed standard deviation of infants' preference for IDS over ADS that corresponds

to infants' language group (either monolingual/bilingual).

$$lnSD \sim 1 + bilingual + ln(d'_z) + (bilingual|lab)$$

where d'_z is the absolute value of d_z because we needed to ensure that values entered into the

logarithm were positive, bilingual is the binary dummy variable that indicates bilingualism -

whether the language group is monolingual or bilingual. Further, we entered a random slope

for bilingualism in the model.

In the lab-matched dataset, we did not find statistically significant evidence for

bilingualism as a moderator of the differences in standard deviations across language groups,

(d_z = -0.08, p = .235). Similarly, we also did not find statistical significance for bilingualism

in the full dataset, (d_z = 0.03, p = .660). In short, we did not find support for the hypothesis

that bilingual infants would show larger within-group variability than monolingual infants.

Mixed-effects approach.   Mixed-effects regression allows variables of interest to be

specified on a trial-by-trial and infant-by-infant basis. We had anticipated that we would be

able to include additional data from labs that aimed to test homogeneous samples (i.e.,

because we could include infants from these labs who were not learning this homogeneous

language pair), but in practice this did not apply as only one lab contributed a homogeneous

data set, and that lab did not test additional infants. We were also able to include data from

all valid trials, rather than excluding data from yoked pairs with a missing data point. As

under the meta-analytic approach, we ran the models twice, once including only data from

labs that contributed lab-matched samples of monolinguals and bilinguals, and once

803 including all available data from 6-9 and 12-15 month-olds.

804   The mixed-effects model was specified as follows:

$$DV \sim IV_1 + IV_2 + ... + (...|\text{subject}) + (...|\text{item}) + (...|\text{lab})$$

805   The goal of this framework was to examine effects of the independent variables (IV) on

806 the dependent variable (DV), while controlling for variation in both the DV ("random

807 intercepts") and the relationship of the IV to the DV ("random slopes") based on relevant

808 grouping units (subjects, items, and labs). Following recent recommendations (Barr, Levy,

809 Scheepers, & Tily, 2013), we planned to initially fit a maximal random effects structure, such

810 that all random effects appropriate for our design were included in the model. However, we

811 also recognized that such a large random effects structure might be overly complex given our

812 data, and would be unlikely to converge. After reviewer feedback during Stage 1 of the

813 Registered Report review process, we pre-registered a plan to use a "Parsimonious mixed

814 models" approach for pruning the random effects (Bates et al., 2015a; Matuschek, Kliegl,

815 Vasishth, Baayen, & Bates, 2017). However, we found that it was computationally difficult to

816 first fit complex models (i.e., our models had multiple interactions and cross-levels grouping)

817 under the maximal random effects structure and then prune the models using a parsimonious

818 mixed models approach. Further, we note that this was not the approach used in

819 ManyBabies 1, which would make direct comparison between ManyBabies 1 and the current

820 study difficult. As such, following ManyBabies 1, we fitted and pruned[2] the following models

821 using the maximal random effects structure only (Barr et al., 2013). We fit all models using

822 the lme4 package (Bates et al., 2015b) and computed p values using the lmerTest package

823 (Kuznetsova, Brockhoff, & Christensen, 2016). All steps of the pruning process we followed

824 are detailed in the analytic code on our Github repository. Following a reviewer's suggestion

---

[2]Results reported in this paper were pruned by fitting mixed-effect models with 'lme4' version 1.1-21.

825 during Stage 2 review (i.e., this had not been pre-registratered), we checked our models for

826 potential issues with multicollinearity by examining variance inflation factors (VIF) for each

827 model. Variables that have VIF values exceeding 10 are regarded as violating the

828 multicollinearity assumption (Curto & Pinto, 2011). None of our models violated this

829 assumption. Below is a description of our variables for the mixed-effects models:

830 • log_lt: Dependent variable. Log-transformed looking time in seconds.

831 • trial_type: A dummy coded variable with two levels, with ADS trials as the baseline,

832   such that positive effects of trial type indicate longer looking to IDS.

833 • bilingual: A dummy coded variable with two levels, with monolingual as the baseline,

834   such that positive effects of bilingualism reflect longer looking by bilinguals.

835 • language: A dummy coded variable for whether infants were learning North American

836   English as a native language (i.e., $>= 90\%$ exposure to NAE for monolinguals, or $>=$

837   25% exposure to NAE for bilinguals).

838 • exp_nae: A continuous variable for the percent of time infants heard North-American

839   English.

840 • method: A dummy-coded variable to control for effects of different experimental

841   setups, with single-screen central fixation as the reference level.

842 • age_days: Centered for interpretability of main effects.

843 • trial_number: The number of the trial pair, recoded such that the first trial pair is 0.

844 • ses: The number of years of maternal education, centered for ease of interpretation.

845 Note that in this analysis plan, we have used a concise format for model specification,

846 which is the form used in R. As such, lower-order effects subsumed by interactions are

847 modeled even though they are not explicitly written. For example, the interaction trial_type

848 * trial_num also assumes a global intercept, a main effect of trial type, and a main effect of

849 trial number.

850 ***Homogeneity of variance.***

851   We pre-registered a Levene's test to examine whether monolinguals and bilinguals

852 showed different amounts of variance in their IDS preference. Our analysis focused on the

853 residual variance for monolinguals and bilinguals in the main linear mixed-effects models, in

854 order to partition out variance associated with other actors (e.g., age, method, etc.). The

855 Levene's test revealed a statistically significant difference in variance for the full samples (p

856 $= 0.02$) but not the lab-matched samples ($p = 0.68$). We note that the difference in residual

857 variances between monolingual (variance $= 0.24$) and bilingual language groups (variance $=$

858 0.25) was small, suggesting that the statistical significance in the Levene's test for the full

859 samples was mainly driven by a larger sample size, not by the differences between

860 monolinguals and bilinguals.

861   ***Effects of bilingualism on IDS preference.***

862   We planned a mixed-effects model which was based on the structure of the final model

863 fit for the ManyBabies project, including bilingualism as an additional moderator. Note that

864 because data collection for both projects was simultaneous, we did not know prior to

865 registration what the final model structure for the monolingual-only sample would be (it was

866 expected that pruning of this model would be necessary in the case of non-convergence). The

867 original model proposed for the monolingual-only sample was designed to include simple

868 effects of trial type, method, language (infants exposed vs. not exposed to NAE-IDS), age,

869 and trial number, capturing the basic effects of each parameter on looking time (e.g., longer

870 looking times for IDS, shorter looking times on later trials). Additionally, the model included

871 two-way interactions of trial type with method and with trial number, a two-way interaction

872 of age with trial number, as well as two- and three-way interactions between trial type, age,

873 and language (see ManyBabies Consortium, n.d., for full justification). This model was

874 specified to minimize higher-order interactions while preserving theoretically-important

875 interactions. Note that to reduce model complexity, both developmental effects and trial

876 effects are treated linearly. The planned initial model was:

$$\log \text{lt} \sim \text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num}+$$
$$\text{trial type} * \text{age} * \text{language}+$$
$$(\text{trial type} * \text{trial num} \mid \text{subid})+ \tag{1}$$
$$(\text{trial type} * \text{age} \mid \text{lab})+$$
$$(\text{method} + \text{age} * \text{language} \mid \text{item})$$

It was expected that pruning would be necessary in the case of non-convergence.

Our analysis plan specified that we would add bilingualism to the fixed effects of the final pruned model that fitted to the monolingual sample. For higher-order interactions in the model, we ensured that we had at least 20 infants per group. For example, for a three-way interaction between bilingualism, language and age, we included at least 20 infants per group: at least 20 infants in the group of 6-9 month-old bilinguals who were not exposed to NAE. We applied the same rules to all other groups.

In our preregistration, we were uncertain as to whether our sample size would support a model with a four-way-interaction of trial type, age, bilingual status, and language. Given our final sample size, we elected to fit our main model without including the four-way interaction effect[3]. In our main model, we included two fixed three-way interactions: (i) the interaction between bilingualism, age and trial type, and (ii) the interaction between language, age and trial type, as well as other subsumed lower-order interactions.

Regardless of our fixed effect structure, the model included the random slope of bilingualism on lab and item, as well as appropriate interactions with other random factors. Our initial unpruned model was:

---

[3]We did not enter the above-mentioned four-way interaction into our main model, but note that in the more complex model, the four-way interaction was not statistically significant in the matched dataset ($\beta = 0.00$, $SE = 0.02$, $p = 0.85$) or the full dataset ($\beta = 0.01$, $SE = 0.01$, $p = 0.63$).

$$\begin{aligned}
\log \text{lt} \sim &\ \text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num} + \\
&\ \text{trial type} * \text{age} * \text{language} + \\
&\ \text{trial type} * \text{age} * \text{bilingual} + \\
&\ (\text{trial type} * \text{trial num} \mid \text{subid}) + \\
&\ (\text{trial type} * \text{age} * \text{bilingual} \mid \text{lab}) + \\
&\ (\text{method} + \text{age} * \text{language} + \text{age} * \text{bilingual} \mid \text{item})
\end{aligned} \tag{2}$$

After pruning random effects for non-convergence and singularity, the final models for the lab-matched dataset and full dataset were different. The following was the final model of the lab-matched dataset:

$$\begin{aligned}
\log \text{lt} \sim &\ \text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num} + \\
&\ \text{trial type} * \text{age} * \text{language} + \\
&\ \text{trial type} * \text{age} * \text{bilingual} + \\
&\ (1 \mid \text{subid}) + \\
&\ (\text{bilingual} \mid \text{lab}) + \\
&\ (1 \mid \text{item})
\end{aligned} \tag{3}$$

In contrast, the final model of the full dataset was:

$$\log \text{lt} \sim \text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num} +$$
$$\text{trial type} * \text{age} * \text{language} +$$
$$\text{trial type} * \text{age} * \text{bilingual} +$$
$$(1 \mid \text{subid}) +$$
$$(1 \mid \text{lab}) +$$
$$(1 \mid \text{item}) \tag{4}$$

Overall, the mixed-level analyses in both lab-matched and full datasets yielded similar results (Table 2 and 3). More coefficients were statistically significant in the full dataset, likely due to the larger sample size. Thus, in the following, we focus on the results of the mixed-level model for the full dataset. We found that infants showed a preference for IDS, as indicated by a positive coefficient on the IDS predictor (reflecting greater looking times to IDS stimuli). We did not find any effects of the bilingualism on IDS preference nor any interaction effects between bilingualism and other moderators. This finding is consistent with the results of our meta-analysis above.

Surprisingly, the fitted model did not show an interaction between infants' IDS preference and the method used in the lab, a result that is different from the results in the ManyBabies 1 project. However, this finding is likely due to smaller sample sizes in the current paper, as we restricted the analysis to participants at particular ages. Apart from this, our findings were largely consistent with the ManyBabies 1 study. There was a significant and positive two-way interaction between IDS and NAE, suggesting greater IDS preferences for children in NAE contexts. The interaction between IDS and age was also significant and positive, suggesting that older children showed a stronger IDS preference. Finally, we found a marginally significant three-way interaction between IDS, age, and NAE, suggesting that older children in NAE contexts tended to show stronger IDS preference than those in the non-NAE contexts.

916   ***Dose effects of exposure to NAE-IDS in bilingual infants.***

917   In this analysis, we tested whether we could observe a dose-response relationship

918   between infants' exposure to NAE-IDS (measured continuously) and their preference for IDS

919   over ADS.

920   We decided to conduct this analysis only including data from bilinguals. Our reasoning

921   was that bilingualism status and exposure to NAE-IDS are confounded, as monolinguals'

922   exposure to NAE will be either near 0% or 100%, while bilinguals' NAE experience can be

923   either 0%, or 25-75%. Because the monolingual sample is larger and their NAE exposures

924   are more extreme, their effects would dominate that of the bilinguals in a merged analysis.

925   Therefore, we reasoned that if there is a dose effect, it should be observable in the bilingual

926   sample alone. Finally, although excluding monolingual infants reduced power overall, we

927   decided that given the relatively large sample of bilingual infants, this disadvantage would be

928   offset by the ease of interpretation afforded by restricting the analysis to bilinguals. On

929   average, bilingual infants in our sample were exposed to 20.17% NAE (range: 0 to 75%).

930   Once again, we based this model on the final pruned monolingual model, substituting

931   the binary measure of exposure to NAE-IDS (language) with the continuous measure of

932   exposure(exp_nae), and including a random slope for exp_nae by item (which was

933   ultimately pruned from the model). After pruning, our model was specified as follows:

$$
\begin{aligned}
\log \text{lt} \sim & \text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num} + \\
& \text{trial type} * \text{age} * \text{exp nae} + \\
& (1 \mid \text{subid}) + \\
& (\text{trial type} \mid \text{lab}) + \\
& (1 \mid \text{item})
\end{aligned} \tag{5}
$$

N		333		

934   Table 4 contains the details of the results in this model. The main effect of infants'

935 exposure to NAE (exp_nae) was not significant ($\beta =$, $SE = $, $p =$). This indicates that

936 bilingual infants who were exposed to more NAE did not pay more attention to the NAE

937 speech stimuli than those who were exposed to less NAE. However, the interaction between

938 trial type and exp_nae was significant ($\beta =$, $SE = $, $p =$). That is, bilingual infants who

939 were exposed to more NAE showed stronger IDS preferences, confirming a dose-response

940 relationship between infants' exposure to NAE and their preference for IDS over ADS

941 (Figure 2) even among bilinguals who are learning NAE as one of their native languages.
Figure 2. Linear trend between infants' IDS preference and their percentage of time exposed to NAE. Blue line indicates a regression model between infants' IDS preference and their NAE exposure (starting from zero). Red line indicates another regression model of the same relationship with a focus of NAE exposure between 25 to 75%. Finally, we note that the y-axis was truncated to highlight the trend such that some individual points are not plotted.

Socio-economic status as a moderator of monolingual-bilingual differences.

Because socio-economic status can vary systematically between monolinguals and bilinguals in the same community, we were interested in whether relationships between bilingualism and IDS preference would hold when controlling for socio-economic status. It is possible that an observed effect of bilingualism on IDS preference could disappear once SES was controlled. Alternatively, it is possible that the effect of bilingualism on IDS preference could only be apparent once SES was controlled. Thus, this analysis was important regardless of an observed relationship between IDS preference and bilingualism in the previous model.

Our approach was to add SES as a moderator of our final model for bilinguals. We expected that any effects of socio-economic status could interact with age, thus this model included interactions of trial type, age, and socio-economic status as a fixed effect, as well as the corresponding random slope by item. Based on the potential model detailed above for the bilinguals, our expected ses-mediated model was:

$$
\begin{aligned}
\log \text{lt} \sim &\text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num}+ \\
&\text{trial type} * \text{age} * \text{language}+ \\
&\text{trial type} * \text{age} * \text{bilingual}+ \\
&\text{trial type} * \text{age} * \text{ses}+ \\
&(\text{trial type} * \text{trial num} \mid \text{subid})+ \\
&(\text{trial type} * \text{age} * \text{bilingual} \mid \text{lab})+ \\
&(\text{method} + \text{age} * \text{language} + \text{age} * \text{bilingual} + \text{age} * \text{ses} \mid \text{item})
\end{aligned}
\tag{6}
$$

After pruning for non-convergence, our final model specifications are listed below. For the lab-matched dataset, the final model was:

$$\begin{aligned}
\log \mathrm{lt} \sim & \text{ trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num}+ \\
& \text{trial type} * \text{age} * \text{language}+ \\
& \text{trial type} * \text{age} * \text{bilingual}+ \\
& \text{trial type} * \text{age} * \text{ses}+ \\
& (1 \mid \text{subid})+ \\
& (\text{bilingual} \mid \text{lab})
\end{aligned} \tag{7}$$

By contrast, the final model of the full dataset was:

$$\begin{aligned}
\log \mathrm{lt} \sim & \text{ trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num}+ \\
& \text{trial type} * \text{age} * \text{language}+ \\
& \text{trial type} * \text{age} * \text{bilingual}+ \\
& \text{trial type} * \text{age} * \text{ses}+ \\
& (1 \mid \text{subid})+ \\
& (1 \mid \text{lab})+ \\
& (1 \mid \text{item})
\end{aligned} \tag{8}$$

In general, across the lab-matched and full datasets (Table 5 and 6), SES did not have a significant effect on infants' looking time nor did it affect infants' preference for IDS. However, for the lab-matched dataset only, we found a statistically significant three-way interaction between IDS, age, and SES. Specifically, infants from 6- to 9-month-olds showed stronger IDS preference when they were from a higher SES families, but older infants from 12- to 15-month-olds showed similar IDS preference across families with different SES levels. However, this interaction was not observed in the full dataset, raising the possibility that it is a spurious, and arose only in the lab-matched dataset because it is substantially smaller than the full data set.

₉₆₉ **Exploratory analyses**

₉₇₀ **The relationship between NAE and IDS for bilingual infants who have**

₉₇₁ **some exposure to NAE.**   In our second confirmatory analysis model (linear mixed model

₉₇₂ 2), we found that bilingual infants with more exposure to NAE showed stronger IDS

₉₇₃ preference. However, this initial analysis included a number of bilingual infants who were not

₉₇₄ exposed to NAE at all (Figure 2). This raises the question of whether the relation between

₉₇₅ NAE and IDS preference may be primarily driven by the infants who were not learning NAE.

₉₇₆ In the following analysis, we re-ran the pre-registered NAE-IDS model by restricting the

₉₇₇ model to infants who were exposed to NAE between 25% and 75% of the time. After

₉₇₈ pruning for non-convergence, the final model was:

$$
\begin{aligned}
\log \text{lt} \sim &\text{trial type} * \text{method} + \text{trial type} * \text{trial num} + \text{age} * \text{trial num}+ \\
&\text{trial type} * \text{age} * \text{exp nae}+ \\
&(1 \mid \text{subid})+ \\
&(1 \mid \text{lab})+ \\
&(1 \mid \text{item})
\end{aligned} \tag{9}
$$

₉₇₉ Based on 135 infants, the interaction between Trial Type and NAE exposure was still

₉₈₀ statistically significant ($\beta = $, \$SE = \$, $p =$). This result suggested that a dose-response

₉₈₁ relationship between infants' exposure to NAE and their preference for IDS over ADS was

₉₈₂ not driven by infants living in non-NAE contexts alone (see Table 7 for details of the model).

₉₈₃ <div align="center">**General Discussion**</div>

₉₈₄ The current study was designed to better understand the effects of experience on the

₉₈₅ tuning of infants' preference for infant-directed speech (IDS) compared to adult-directed

Table 7

speech (ADS). Bilingual infants' language experience is split across input in two different languages, which are being acquired simultaneously. Bilinguals and monolinguals may thus differ in their preference for IDS. To explore this question, we used a collaborative, multi-lab (N = 17 labs) approach to gather a large dataset of infants who were either 6-9- or 12-15-months old and growing up bilingual (N = 333 bilingual infants in the final sample, and a lab-matched sample of N = 385 monolingual infants from the same communities). Data were collected as a companion project to ManyBabies 1 (ManyBabies Consortium, n.d.), which was limited to infants growing up monolingual. Overall, we found that bilingualism neither enhanced nor attenuated infants' preference for IDS, with bilinguals showing a similar magnitude and developmental trajectory of IDS preference as monolinguals from age 6 to 15 months.

Although bilingual experience did not appear to moderate infants' preference for IDS, we found striking evidence that experience hearing North-American English (NAE, the language of our stimuli) contributed to the magnitude of bilingual infants' IDS preference. Bilinguals with greater exposure to NAE showed greater IDS preferences (when tested in NAE) than those who had less exposure to NAE. This relationship between NAE exposure and IDS preference was also observed in a subsample of bilingual infants all acquiring NAE, but who varied in how much they were exposed to NAE relative to their other native language. These results converge with those from the larger ManyBabies 1 study, which reported that monolinguals acquiring NAE had a stronger preference for IDS than monolinguals acquiring another language. Importantly, our approach provides a more nuanced view of the relationship between NAE and IDS preference, and suggests that there is a continuous dose effect of exposure on preference. Together, our findings have a number of implications for bilingual language acquisition during infancy. In the following, we will first discuss each of our research questions in turn, followed by limitations and implications of our study.

1012   Our first research question asked whether bilingualism affects infants' attention to IDS

1013 relative to ADS. We hypothesized that the complexity of the bilingual infant's learning

1014 experience might lead to greater reliance on/preference for IDS, given that IDS may be

1015 viewed as an enhanced linguistic signal. However, this hypothesis was not confirmed. We

1016 observed a meta-analytic effect size in the full dataset for monolinguals of $d_z = 0.36$ [CI =

1017 0.28, 0.44] and for bilinguals of $d_z = 0.26$ [CI: 0.09, 0.43]. While monolinguals showed a

1018 numerically larger effect size, this difference was not statistically significant in either the

1019 meta-analyses or the mixed-effects linear models. Although small differences are still

1020 possible, our data generally support the conclusion that bilingual and monolingual infants

1021 show a similar preference for IDS over ADS. Specifically, both groups show a preference for

1022 IDS at 6-9 months of age, which gets stronger by 12-15 months.

1023   An additional part of our first research question asked whether bilinguals might show

1024 more variability than monolinguals in their IDS preference, beyond any differences in the

1025 magnitude of the preference. We had reasoned that given their diversity of language

1026 experiences, bilingual groups may have a higher heterogeneity in terms of their IDS

1027 preference compared to monolingual groups (see also Orena & Polka, 2019, for a recent

1028 experiment that observed this pattern). Both monolingual and bilingual groups showed high

1029 variability. The magnitude of the observed difference in variability was very small. We

1030 carried three analyses to compare the variability between the monolinguals and bilinguals.

1031 Only one of the three variability analyses (i.e., the mixed effect model in the full dataset)

1032 was statistically significant. This statistical significance was mainly driven by the large

1033 sample size in the full dataset ($N = 1754$) because the difference in variability between the

1034 monolinguals and bilinguals remained negligible. Thus, our results did not support the idea

1035 that bilingual infants show meaningfully more variability in theirle IDS preference than their

1036 monolingual peers.

1037   Given that monolinguals and bilinguals can systematically differ in their

socio-economic status (SES), the third part of our first research question asked whether SES might moderate bilingualism effects. Using the years of maternal education as a proxy for SES, we found mixed support for the role of SES in our datasets. In our smaller lab-matched dataset, we found a statistically significant interaction between age, SES, and IDS preference: 6-9-month-olds from higher SES families showed stronger IDS preference than those from lower SES families, whereas 12-15-month-olds showed similar IDS preference regardless of SES. The direction of this effect aligns with other research reporting that children from higher SES families generally receive more language input and/or higher quality input (e.g., engaging in conversations with more lexical diversity, complexity, and structural variations) than children from lower SES families (Fernald, Marchman, & Weisleder, 2013; Hart & Risley, 1995; Hoff, 2006; Tal & Arnon, 2018). Thus, this could suggest that infants from higher SES families may show stronger IDS preference earlier in life as they hear more or higher quality IDS in their daily lives. Further, this positive SES impact may be most beneficial to younger infants whose IDS preference is still developing. However, given that in our larger (full) dataset SES was unrelated to IDS preference in either 6-9- or 12-15-month-olds, this result might be spurious and should be interpreted with caution. Further, it is important to note that our samples (both monolingual and bilingual group) were mainly from higher SES families. Indeed, in the lab-matched dataset, '67.79% of children whose mothers had earned at least a bachelor degree after kindergarten. Our samples therefore have a low variability in SES, thus this question would be better tested with future studies that have participants from more diverse SES backgrounds.

Our second research question asked whether and how the amount of exposure to NAE would affect bilingual infants' listening preferences. Given that our stimuli were produced in NAE, we expected that greater exposure to NAE would be linked to greater attention to NAE IDS relative to NAE ADS. Indeed, ManyBabies 1 (ManyBabies Consortium, n.d.), which was conducted concurrently with the current study, found that monolinguals acquiring NAE showed a stronger IDS preference than monolinguals not acquiring NAE. However, in

the ManyBabies 1 study, exposure to NAE-IDS was a binary variable – either the infants heard only NAE or heard only a different language in their language environments. In the current paper, bilinguals provide a more nuanced way to address this question, as bilinguals' exposure to NAE varied continuously between 25% and 75% (for infants learning NAE as one of their native languages) or was near 0% (for infants learning two non-NAE native languages). We found clear evidence for a positive dose-response relationship between exposure to NAE and infants' preference for NAE-IDS. This evidence – that bilinguals with more exposure to NAE showed a stronger NAE-IDS preference – was also present when focusing only on bilinguals who were learning NAE as one of their native languages (i.e., those exposed to NAE 25-75% of the time). Importantly, we did not find a similar effect of exposure to NAE on infants' overall looking. This suggests that the effect of NAE exposure on preference for IDS is a meaningful relationship, rather than an artefact due to the stimuli being presented in NAE. Further studies with stimuli in other languages would be necessary to solidify this conclusion.

As the first study to recruit and test bilingual infants at such a large scale and at so many sites, we encountered several challenges (see also Byers-Heinlein et al., n.d., for a fuller discussion of challenges in planning and conducting ManyBabies 1). First, several laboratories were not able to recruit the number of bilingual infants they had originally planned. All labs committed to collecting a minimum of 16 bilingual infants per age group. This ended up being unfeasible for some labs within the timeframe available (which was more than a year), in some cases due to a high number of participants not meeting our strict criterion for inclusion as bilingual. This undoubtedly highlights the challenges for labs in recruiting bilingual infant samples, and moreover raises questions about how bilingualism should be defined, and whether it should be treated as a continuous vs. categorical variable (Anderson, Mak, & Bialystok, 2018; Bialystok, Luk, Peets, & Yang, 2018; Incera & McLennan, 2018). Second, we had planned to explore the effect of different language pairs on IDS preference. We had expected that some labs would be able to recruit relatively

homogeneous samples of infants (i.e., all learning the same language pair), but in the end only one of 17 labs did so (another lab had planned to recruit a homogeneous sample but deviated from this plan when it appeared unfeasible). Thus, we leave the question of the effect of language pair on infants' IDS preference an open issue to be followed up in future studies. By and large, we believe that our large-scale approach to data collection may in the future allow for the creation of homogeneous samples of infants tested at different laboratories around the world. As such, large-scale and multi-site bilingual research projects provide researchers with a powerful way to examine how the diversity and variability of bilinguals impact their language and cognitive development.

Overall, our finding that bilinguals show similar preference for IDS as monolinguals reinforces theoretical views that emphasize the similarities in attentional and learning mechanisms across monolingual and bilingual infants (e.g., Curtin, Byers-Heinlein, & Werker, 2011). IDS appears to be a signal that enhances attention in infants from a variety of language backgrounds. Yet, bilingual infants appear to be exquisitely fine-tuned to the relative amount of input in each of their languages. It could have been the case that language exposure has a threshold effect with any regular exposure to NAE enhancing infants' preference for NAE-IDS, marking it is a highly relevant speech signal. Instead, we observed a graded effect such that the magnitude of bilingual infants' preference varied continuously with the amount of exposure to NAE. Just as bilingual infants' relative vocabulary size and early grammar skills in each language are linked to the amount of input in that language (Hoff et al., 2012; Place & Hoff, 2011), the current study shows that the amount of language input may also play an important role in other language acquisition processes. Indeed, an intriguing but untested possibility is that different input-related attentional biases (i.e., IDS preference) across bilinguals' two languages explain important variability in the early development of bilingual children's vocabulary and grammar. Future bilingual work can investigate the above possibility to further delineate the interplay between infants' language input, IDS preference, vocabulary, and grammar skills.

Our inclusion of both a mixed model and a meta-analyses allowed us to compare these two approaches. As our field moves toward more large scale studies of this type, it will be important to determine appropriate standards for analysis. Our meta-analysis allows for better and more direct comparison with prior meta-analysis (e.g., (Dunst et al., 2012)). However, an important limitation of this approach is that infants' data is collapsed to a single data point per group, thus obscuring potentially interesting variability. Moreover, because we could not model trial number directly, this average was based on valid adjacent trial pairs, which resulted in many trials being excluded from the analysis. In contrast, the mixed effect models analyzed data at the individual trial level, allowing us to examine how variability of data can be explained by moderators at the trial and participant level, which increases statistical power. Our finding of a significant age effect in the mixed models, but not in the meta-analysis, can be attributed to this difference in statistical power. Moving forward, we believe that these complementary approaches each have their place, but that the mixed effect model is preferred as it improves statistical power.

To conclude, the findings of the current study provide a more nuanced view of the development of infants' preference for IDS than prior studies have allowed. IDS preference develops along a similar trajectory across infants from monolingual and bilingual backgrounds. Importantly, by testing bilingual infants, our results revealed that this IDS preference operates in a dose-response fashion, where the amount of exposure to NAE positively moderated infants' (NAE-) IDS preference in a continuous way. Our experience highlights the challenges in recruiting and testing bilingual infants, but also reveals the promise of large-scale collaborations for increasing sample sizes, and thus improving the replicability and generalizability of key findings in infant research.
